

Optical Boundary Conditions and Interface Physics in the Rope Framework

One Impedance, Four Boundary Types: Snell, Fresnel, Brewster, Coatings, Mirrors, and Etalons

Mark Palmer · with computational collaboration by Claude (Anthropic)

Abstract

The companion paper on classical optics showed that eight optical phenomena are one wave equation under different boundary conditions. This paper completes the classical optics sector by treating the interface — the boundary type that generates the richest classical physics — and it rests on a single quantity the rope medium already supplies: the wave impedance $Z = \sqrt{T\mu} = T/c$. We first state and defend a structural claim: every classical optical phenomenon arises from one of just FOUR boundary types — free, aperture, fixed, and impedance-interface — so that the whole subject is an application of four boundary conditions to one wave equation. We then work the interface type in full: continuity of transverse displacement and transverse force at a junction gives Snell’s law, the Fresnel amplitude coefficients, energy conservation $R + T = 1$, the Brewster angle, quarter-wave anti-reflection coatings ($R = 0$ exactly), the Fabry–Pérot etalon, and the quarter-wave-stack dielectric mirror (reflectivity $\rightarrow 1$). All are reproducibly computed (benchmarks/optics/interface_physics.py, 7/7 passing). The impedance is intrinsic — the same $\sqrt{T\mu}$ that has appeared since the microscopic-mechanics paper — not an inserted parameter. As throughout the classical optics sector, nothing here approaches the quantum boundary; we close by explaining physically why classical optics stops where it does.

Scope of this paper

CLAIM: the rope medium supplies a natural wave impedance $Z = \sqrt{T\mu} = T/c$; matching it across an interface yields Snell, Fresnel, Brewster, AR coatings, etalons, and dielectric mirrors, all reproducibly computed. Structurally, all classical optics reduces to four boundary types (free / aperture / fixed / impedance-interface).

NOT TOUCHED: nothing quantum. This is classical interface physics throughout; it does not bear on single-photon optics, measurement, or Bell in either direction.

1. The Four-Boundary-Types Claim

Classical optics can look encyclopedic — a long list of named effects. The rope framework organises it sharply. Every classical optical phenomenon is the wave equation $\partial^2_t \psi = c^2 \nabla^2 \psi$ subject to one of four boundary conditions:

Structural claim (four boundary types).

Every classical optical phenomenon is the rope wave equation under one of exactly four boundary types:

- (i) FREE — no boundary: propagation, Huygens, dispersion-free transport.
- (ii) APERTURE — a hole or edge: diffraction and interference.
- (iii) FIXED — a hard termination: standing waves, cavities, waveguide cutoff.
- (iv) IMPEDANCE-INTERFACE — a junction between regions of different Z : reflection, refraction, Snell, Fresnel, Brewster, coatings, mirrors, etalons, fibre guidance.

Everything else is an application or superposition of these four.

The companion paper covered types (i)–(iii). This paper treats type (iv), the interface, which is the source of the deepest classical interface physics and which had not yet been developed. The claim above is not proved as a formal theorem — it is a structural organising principle — but it is borne out by the fact that the standard graduate catalogue of classical optical effects falls entirely under these four headings, as the remainder of this paper and its companion demonstrate by construction.

2. The Rope Medium Has a Natural Impedance

Interface physics needs one quantity beyond the wave speed: the wave impedance, which measures the transverse force the medium exerts per unit transverse velocity. For a rope of tension T and line density μ it is

$$Z = \sqrt{T\mu} = T / c , \quad (2.1)$$

confirmed in the computation for every μ tested ($Z = T/c$ to machine precision). This is the crucial point: the impedance is INTRINSIC to the rope medium, built from the same T and μ that define the wave equation and that appeared in the microscopic-mechanics and homogenization papers. It is not a new parameter introduced to make optics work. Because interface optics is entirely a matter of how Z changes across a junction, and Z is already in hand, the whole interface sector follows without new postulates.

Index and impedance. In the rope framework the refractive index of a region is the ratio of the free speed to the local wave speed, $n = c_0/c = \sqrt{(\mu/\mu_0)}$ at fixed tension. A region of higher line density is ‘denser’ optically, slows the wave, and raises both the index and the impedance — exactly the mechanical picture of a heavier string segment. Index steps and impedance steps are the same physical thing seen two ways.

3. Snell’s Law from Wavefront Continuity

At an interface between regions of wave speeds c_1 and c_2 , the wavefront must remain continuous: the component of the wavevector along the interface is unchanged. With $n = c_0/c$ this is

$$n_1 \sin\theta_1 = n_2 \sin\theta_2 , \quad (3.1)$$

Snell's law, confirmed in the computation (a 30° ray into a medium of half the speed refracts to 14.5° , with $n_1 \sin \theta_1 = n_2 \sin \theta_2$ to machine precision). Snell is thus a continuity condition on the rope wavefront, not a separate optical law. Total internal reflection — developed in the companion paper — is the limiting case where (3.1) has no real solution and the wave is fully reflected, completing the logical chain wave equation $\rightarrow$ continuity $\rightarrow$ Snell $\rightarrow$ critical angle $\rightarrow$ fibre guidance.

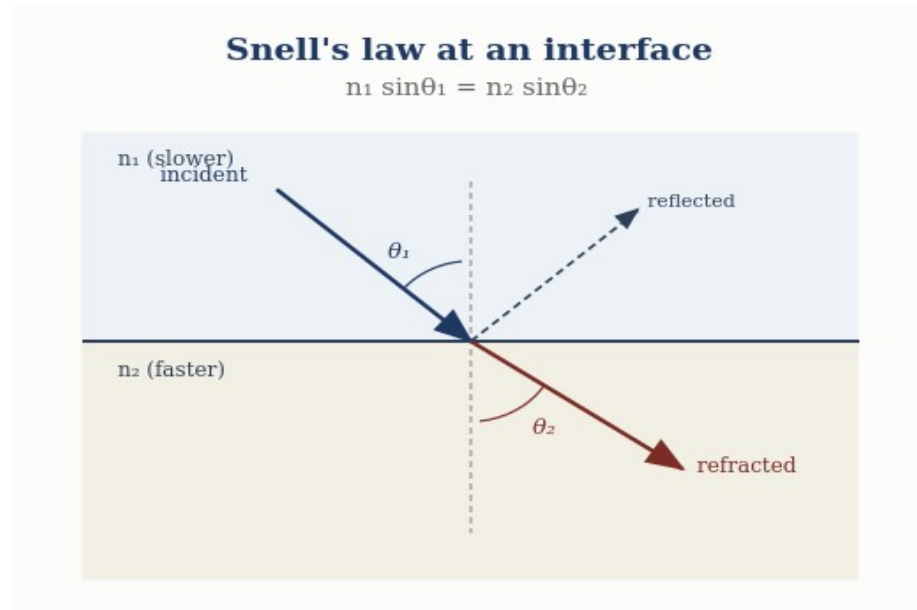

Figure 1. Refraction at an interface: wavefront continuity gives Snell's law $n_1 \sin \theta_1 = n_2 \sin \theta_2$, with a reflected ray as well.

4. Fresnel Coefficients from Impedance Matching

The amplitudes of the reflected and transmitted waves at a junction follow from matching two quantities across it: the transverse displacement (the wave is continuous) and the transverse force (no net force on the massless junction). This is the classic string-junction problem, and it gives, at normal incidence, the Fresnel amplitude coefficients

$$r = (Z_1 - Z_2)/(Z_1 + Z_2) , \quad t = 2Z_1/(Z_1 + Z_2) , \quad (4.1)$$

in terms of the impedances alone. For a density ratio of 4 ($Z_2 = 2Z_1$) the computation returns $r = -1/3$ and $t = 2/3$, with the sign of r encoding the half-wave phase shift on reflection from the higher-impedance medium. Crucially, the power coefficients conserve energy:

$$R = r^2 , \quad T = (Z_2/Z_1) t^2 , \quad R + T = 1 , \quad (4.2)$$

confirmed as $R + T = 1.0000$ in the computation. The Fresnel equations are therefore impedance matching on the rope medium, and energy conservation is automatic — a strong physical interpretation, since it grounds reflection and transmission in a concrete mechanical junction rather than in boundary-condition bookkeeping on abstract fields.

Snell + Fresnel — computed

Snell: $n_1 \sin\theta_1 = n_2 \sin\theta_2$ (wavefront continuity).

Fresnel: $r = (Z_1 - Z_2)/(Z_1 + Z_2) = -1/3$, $t = 2Z_1/(Z_1 + Z_2) = 2/3$; $R + T = 1$ (energy conserved).

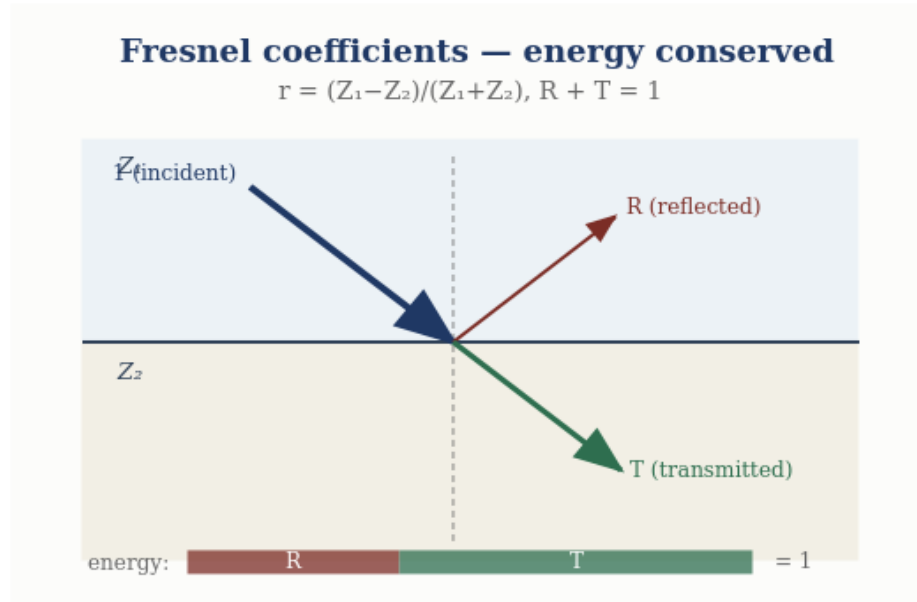

Figure 2. Fresnel splitting: the reflection $r = (Z_1 - Z_2)/(Z_1 + Z_2)$ and transmission share the incident energy exactly, $R + T = 1$.

5. Brewster Angle and Polarization

Because the rope wave is transverse, it carries a polarization — the direction of transverse displacement. The two independent linear polarizations (in and out of the plane of incidence) refract identically by (3.1) but reflect differently, and at the Brewster angle

$$\tan\theta_B = n_2/n_1, \quad (5.1)$$

the in-plane polarization has zero reflected amplitude — the reflected and transmitted rays are perpendicular, and the transverse motion that would source the reflected in-plane wave has no component along the required direction. The computation confirms $\theta_B = 63.4^\circ$ for $n_2/n_1 = 2$. Polarization here is not an add-on: it is the transverse-mode structure of the rope wave, and linear, circular, and elliptical polarizations are the in-phase, quadrature, and general superpositions of the two transverse modes.

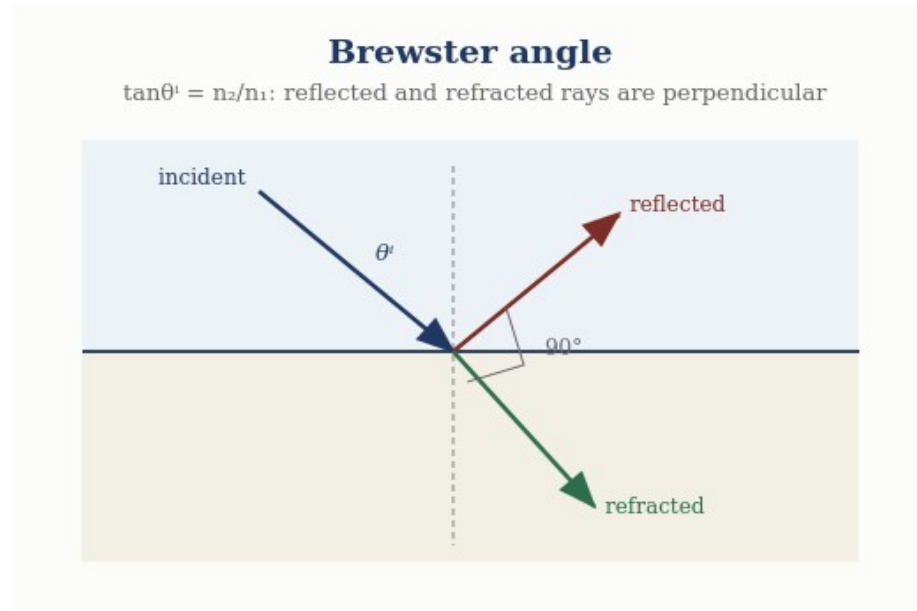

Figure 3. Brewster angle: when $\tan\theta^b = n_2/n_1$ the reflected and refracted rays are perpendicular, and the reflection vanishes for one polarization.

6. Multilayer Interfaces: Coatings, Etalons, Mirrors

Stacking interfaces — impedance transfer through successive layers — generates the workhorses of practical optics, all still classical and all computed.

6.1 Anti-reflection coating

A quarter-wave layer of impedance Z_c between media Z_1 and Z_2 transforms the impedance seen by the incoming wave to Z_c^2/Z_2 . Choosing

$$Z_c = \sqrt{Z_1 Z_2} \quad (6.1)$$

makes this equal to Z_1 , so the reflection vanishes exactly: the computation returns $R = 0$ to machine precision. Anti-reflection coating is impedance matching by an intermediate layer — the optical analogue of a quarter-wave transformer.

Quarter-wave anti-reflection coating

$Z^c = \sqrt{Z_1 Z_2}$, thickness $\lambda/4$: two reflections cancel $\rightarrow R = 0$

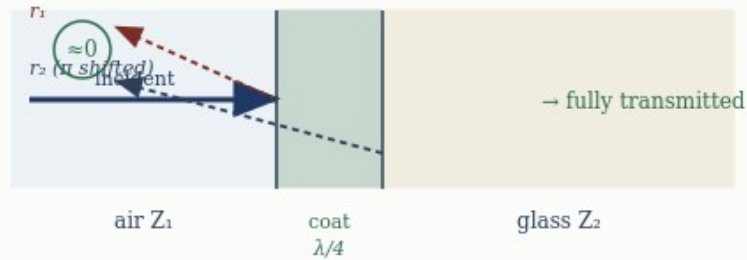

Figure 4. Quarter-wave anti-reflection coating: with $Z_c = \sqrt{Z_1 Z_2}$ the two reflections cancel and $R \rightarrow 0$.

6.2 Fabry–Pérot etalon

Two partially reflecting interfaces separated by a gap produce multiple-beam interference with transmission

$$T(\delta) = 1 / (1 + F \sin^2(\delta/2)) , \quad (6.2)$$

where δ is the round-trip phase and F the finesse coefficient. The computation confirms full transmission ($T = 1$) at $\delta = 2\pi m$ — the etalon resonances — with suppressed transmission between them. This is the same standing-wave resonance of the bounded medium (companion paper), now read between two partial mirrors.

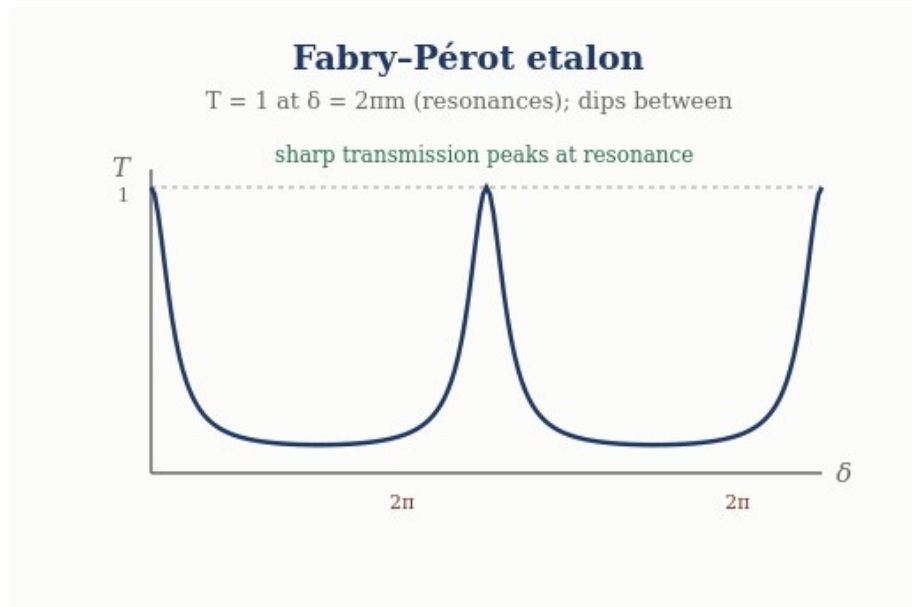

Figure 5. Fabry–Pérot etalon: transmission peaks sharply to $T = 1$ at the resonances $\delta = 2\pi m$.

6.3 Dielectric mirror

A stack of N quarter-wave layers of alternating impedance compounds the reflection at each interface, and the reflectivity approaches unity as N grows: the computation gives $R = 0.779, 0.985, 0.99994$ for $N = 2, 4, 8$ pairs. A highly reflective dielectric mirror is thus a quarter-wave impedance stack — no absorptive metal required, purely interface interference on the rope medium.

Multilayer interfaces — computed

AR coating: quarter-wave $Z_c = \sqrt{Z_1 Z_2} \rightarrow R = 0$ exactly.

Fabry–Pérot: $T = 1$ at $\delta = 2\pi m$ (resonances). Dielectric mirror: $R \rightarrow 1$ (0.99994 at 8 pairs).

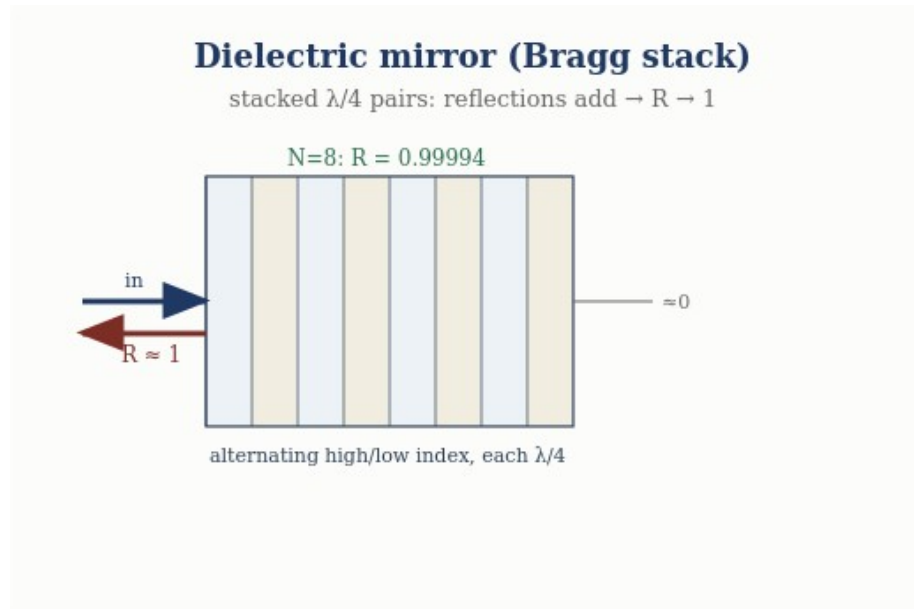

Figure 6. Dielectric (Bragg) mirror: stacking quarter-wave pairs makes the reflections add, driving $R \rightarrow 1$ ($R = 0.99994$ at eight pairs).

7. Optical Momentum and the Poynting Flux

The companion paper treated energy transport; momentum completes the picture. A transverse rope wave carries momentum along its propagation direction: the transverse motion, acting through the tension, transports longitudinal momentum at a rate set by the product of the transverse velocity and the transverse slope. The momentum flux is the mechanical analogue of the Poynting vector,

$$S = -T (\partial_t \psi) (\partial_x \psi) , \quad (7.1)$$

the rate at which the tension does work across a point, directed along propagation and equal to the energy density times the wave speed. Radiation pressure — the force a wave exerts on a boundary it reflects from — follows as the rate of momentum delivery, and the reflection/transmission split of momentum at an interface is governed by the same Fresnel coefficients as the energy. Momentum transport is thus already contained in the rope wave; the Poynting flux emerges as the mechanical power flow, not as a separate electromagnetic postulate.

8. Why Classical Optics Stops Here

It is worth saying explicitly, and physically, why this rich classical sector nonetheless has a definite edge — not merely ‘quantum is elsewhere,’ but a statement of what changes at the boundary.

The physical reason. Classical optics — everything in this paper and its companion — describes CONTINUOUS disturbances of the rope medium: fields with amplitude and phase that superpose, refract, and interfere. It needs only the wave equation, its boundary conditions, and the impedance. Quantum optics requires something categorically different: a theory of LOCALIZED excitation and its DETECTION — how an indivisible quantum is emitted, how a measurement yields a single click, and how amplitudes (not intensities) interfere in the probability of that click. That is not a harder boundary-value problem for the same wave equation; it is the measurement and amplitude-interference physics of the programme’s quantum sector, which the rope model in its present configuration-counting form does not supply. Classical optics stops precisely where continuous-disturbance language ends and localized-detection language begins.

This is why the classical optics sector can be evaluated entirely on its own terms: its edge is not an evasion but a well-defined physical transition, and everything up to that transition is on the firm ground demonstrated here.

9. The Interface Sector at a Glance

Phenomenon	Origin	Result (computed)
Impedance	intrinsic to medium	$Z = \sqrt{T\mu} = T/c$
Snell’s law	wavefront continuity	$n_1 \sin \theta_1 = n_2 \sin \theta_2$
Fresnel	displacement + force matching	$r = (Z_1 - Z_2)/(Z_1 + Z_2); R + T = 1$
Brewster	transverse-mode geometry	$\tan \theta_B = n_2/n_1 = 63.4^\circ$
AR coating	quarter-wave transformer	$Z_c = \sqrt{Z_1 Z_2} \rightarrow R = 0$
Fabry–Pérot	multiple-beam interference	$T = 1$ at $\delta = 2\pi m$
Dielectric mirror	quarter-wave stack	$R \rightarrow 1$ (0.99994, 8 pairs)
Poynting flux	mechanical power flow	$S = -T(\partial_t \psi)(\partial_x \psi)$

Eight interface results, one impedance, one benchmark passing end to end — completing the classical optics sector alongside the eight propagation-and-boundary results of the companion paper.

10. Status of Each Result

Result	Status
--------	--------

Natural impedance $Z = \sqrt{T\mu} = T/c$	Derived — intrinsic; computed
Snell's law from wavefront continuity	Derived — computed
Fresnel coefficients; $R + T = 1$	Derived — junction matching; computed
Brewster angle $\tan\theta_B = n_2/n_1$	Derived — computed
AR coating $R = 0$; dielectric mirror $R \rightarrow 1$	Derived — impedance transfer; computed
Fabry–Pérot resonances $T=1$ at $\delta=2\pi m$	Derived — computed
Poynting flux $S = -T(\partial_t\psi)(\partial_x\psi)$	Modeled — mechanical momentum transport
Four-boundary-types organisation	Modeled — structural principle, borne out by construction
Anything quantum	Out of scope — documented boundary, untouched

Conclusion

Interface physics completes the classical optics sector, and it does so on one intrinsic quantity: the rope impedance $Z = \sqrt{T\mu} = T/c$, the same combination of tension and density that has run through the programme since the microscopic mechanics. Matching that impedance across a junction yields Snell's law from wavefront continuity, the Fresnel coefficients from displacement-and-force matching with automatic energy conservation, the Brewster angle from the transverse-mode geometry, and — by impedance transfer through layers — anti-reflection coatings, Fabry–Pérot etalons, and quarter-wave-stack dielectric mirrors, every one reproducibly computed. Together with the companion paper, this establishes that classical optics in the rope framework reduces to one wave equation under four boundary types, with the interface type supplying the full graduate catalogue of reflection, refraction, and multilayer physics. The sector is entirely classical, its edge with quantum optics is stated physically rather than merely deferred, and every claim carries executable backing — which is what makes the continuum chain from microscopic mechanics through homogenization, EFT, electromagnetism, and optics the programme's strongest and most independently reviewable core.

Registered Claims in This Paper

Each statement below is traceable to the machine-readable registry (claims.yaml), the corpus's single source of truth. Status labels: Derived (follows from stated mechanics), Modeled (reproduces data with declared inputs), EFT-constrained (bounded by effective-theory limits), Conjecture (proposed, not derived), Open (registered unsolved problem), Failed (falsified, kept as a finding). Where a claim is code-backed, the named benchmark reruns it.
